(Received ?; revised ?; accepted ?.)

The ballooning magnetohydrodynamic (MHD) modes have been often suggested as a possible instability trigger of the substorm onset, and a mechanism of compressional waves in the outer magnetosphere and magnetotail. Commonly these disturbances are characterized by the local dispersion equation which is widely applied for the description of ULF oscillatory disturbances and instabilities in the nightside magnetosphere. In realistic situations, especially in the inner magnetosphere, the magnetospheric plasma is composed of two components: background "cold" plasma and "hot" component. The ballooning disturbances in a two-component plasma immersed into a curved magnetic field are described with the system of coupled equations for the Alfvén and slow magnetosonic modes. We have reduced the basic system of MHD equations to the dispersion equation for the small-scale in transverse direction disturbances, and applied WKB approximation along a field line. As a result, we have derived a dispersion equation which can be used for geophysical applications. In particular, from this relationship the dispersion, instability threshold, and stop-bands of the Alfvén and slow magnetosonic modes in two-component plasma have been examined.

1. Introduction: Ballooning modes in the near-Earth plasma

The ballooning instability could be a possible trigger of the substorm explosive phase as was suggested by Miura \textit{et al.} (1989) and Ohtani & Tamao (1993). Later this idea was extensively elaborated (Liu 1997; Cheng & Qian 1994; Agapitov 2007). Favorable conditions for the growth of this instability emerge at a steep plasma pressure drop held by curved field lines. Such a condition may occur before substorm onset on strongly extended field lines (Zhu \textit{et al.} 2009). Though the main substorm power is released via reconnection in the distant magnetotail, the substorm onset trigger could be the ballooning instability in a region of closed field lines (Raeder \textit{et al.} 2010). There are other magnetospheric regions where the ballooning instability may develop: outer boundary of the trapped radiation (Pokotelov \textit{et al.} 1980), at the westward travelling surge (Roux \textit{et al.} 1991). This instability can be imagined as a localized disruption of plasma pressure gradient by growing small-scale "fingers" of hot plasma. To better understand the physical mechanisms of the processes involved in the substorm development, the results of the numerical modeling and \textit{in situ} satellite observations are to be compared with simplified, but more explicit, theoretical models.

Ultra-Low-Frequency (ULF) waves of the Pc5 frequency range (periods about 3 − 10 min) — so called storm-time Pc5 pulsations, — are a ubiquitous element of magnetic

† Email address for correspondence: pilipenk@augsburg.edu
storms. These long-lasting (from several hours to tens of hours) monochromatic oscillations are supposedly generated by ring current protons during the magnetic storm recovery phase. A feature of these pulsations is a significant field-aligned (compressional) magnetic component and small azimuthal scale (wave numbers $m \approx 30 - 100$). Many theories (e.g., Southwood & Saunders 1985; Cheremnykh & Parnowski 2004) were aimed to understand the physics of compressional Pc5 waves persistently observed by space-borne magnetometers. Various kinds of kinetic instabilities of ring current ions were suggested as a possible excitation mechanism of these waves (Pokhotelov et al. 1985; Cheng & Lin 1987; Cheng et al. 1994).

ULF waves also play an active role in the dynamics (energy transport, dissipation, and sink) of the Earth’s magnetotail (Keiling 2009). Geotail satellite observations in the magnetotail from 9 to 30 $R_E$ indicated coupling of slow mode and transverse Alfvén wave (Nakamizo & Iijima 2003). The mode conversion between the Alfvén and slow mode waves were observed by the THEMIS spacecraft constellation in the region of the central current sheet (Du et al. 2011). Thus, coupled MHD modes are a vital component of dynamic magnetotail and outer magnetosphere. The ballooning MHD instability was suggested to be a trigger for the destabilization of the solar coronal loops and flare energy release (Tsap et al. 2008).

A theoretical approach to the study of the ballooning modes and their stability is based on a complicated system of coupled equations for the poloidal Alfvén waves and slow magnetosonic (SMS) modes in a finite-pressure plasma immersed in a curved magnetic field $B$. The easiest way to comprehend qualitatively the basic features of the unstable modes and instability condition is the analysis of a local dispersion equation. Such a dispersion equation, obtained using a local analysis of this system, is widely used for geophysical applications both for examination of plasma stability (Liu 1997), and for the description of spectral properties of ULF wave phenomena in the nightside auroral magnetosphere (Safargaleev & Maltsev 1986; Golovchanskaya & Mingalev 2006). The most detailed and comprehensive derivation and analysis of the dispersion equation was provided by (Mazur et al. 2012).

However, in all above papers it was assumed that plasma had one component with a finite temperature. In realistic situations, especially in the outer magnetosphere, the magnetospheric plasma is composed of two components (Walker 1987):

- background "cold" plasma with density $\rho_{c0}$;

- "hot" component with density $\rho_{h0}$ which is responsible for a finite plasma pressure.

The two-component plasma may be characterized e.g. by the fraction of the hot component $\mu = \rho_{h0}/(\rho_{c0} + \rho_{h0})$ (for one-component plasma $\mu = 1$).

Moreover, the previous studies considered 2D geometry, where the coordinate lines were straight in $Y$ (azimuthal) direction. In reality, the magnetospheric system is torus-like, therefore, the magnetic shell curvature in the azimuthal direction may influence the wave properties. In this paper we derive and analyze the dispersion equation with the account of these aspects: two-component plasma and curved magnetic shells in the azimuthal direction.
2. MHD plasma equilibrium and linearized dynamic equations

2.1. Basic equations

We consider the plasma consisting of cold and hot ions in a curvilinear magnetic field. The set of MHD equations in this case is (Walker 1987):

\[
\begin{align*}
\frac{dV_h}{dt} &= -\nabla P + c^{-1}J_h \times B, \quad (2.1) \\
\frac{\partial \rho_h}{\partial t} + \nabla \rho_h V_h &= 0, \quad (2.2) \\
\rho_c \frac{dV_c}{dt} &= c^{-1}J_c \times B, \quad (2.3) \\
\frac{d}{dt} \left( \frac{P}{\rho_h} \right) &= 0, \quad (2.4) \\
\nabla \times E &= -c^{-1} \frac{\partial B}{\partial t}, \quad \nabla \times B = 4\pi c^{-1}(J_h + J_c), \quad (2.5) \\
E &= -c^{-1}V_c \times B = -c^{-1}V_h \times B, \quad (2.6)
\end{align*}
\]

where \(V_{c,h}\) and \(\rho_{c,h}\) are the velocities and densities of cold and hot plasma components, \(P\) is the plasma pressure, \(B\) is the magnetic field, \(J_{c,h}\) is the current density transported by cold and hot particles, \(E\) is the electric field, \(\gamma\) is the adiabatic index, and \(d/dt = \partial/\partial t + (V \nabla)\) is the Lagrangian derivative. Thus, it was supposed that in MHD limit both cold and hot particles oscillate in a wave electric field with the same transverse velocity, implying the frozen-in condition (Walker 1987).

We introduce the right-handed orthogonal curvilinear coordinates associated with the background axisymmetric magnetic field geometry \(B_0\): the \(x^3\) coordinate is directed along the background magnetic field, therefore, \(B_0 = (0, 0, B_0)\), where \(B_0\) is the scaled component of \(B_0\), the \(x^1\) coordinate is across magnetic shells, and the \(x^2\) coordinate is in the azimuthal direction.

Assuming that plasma is immobile in the stationary state, \(V_{0c} = V_{0h} = 0\), we get the local equilibrium condition:

\[
\nabla_1 P_0 + \frac{1}{4\pi} h_3^{-1} B_0 \nabla_1 h_3 B_0 = 0, \quad (2.7)
\]

where \(\nabla_i = h_i^{-1} \partial/\partial x^i\), \(h_i = \sqrt{g_i}\) are scale factors, and \(g_i \equiv g_{ii}\) are diagonal components of the metric tensor. The condition (2.7) can be written in terms of \(\kappa\)-parameters:

\[
(\beta/2) \kappa_P + \kappa_B - \kappa_c = 0,
\]

where \(\kappa_P = \nabla_1 \ln P_0\), \(\kappa_B = \nabla_1 \ln B_0\), \(\kappa_c = -\nabla_1 \ln h_3\) is the curvature of magnetic field line, \(\beta = 8\pi P_0/B_0^2\). The pressure \(P_0\) is constant along the field line, \(\nabla_3 P_0 = 0\). Due to axial symmetry of medium, all the unperturbed parameters are uniform in the azimuthal direction.

We introduce the displacement vectors \(\xi_{c,h}\) and linearize the set of equations (2.1)–(2.6) with respect to the small monochromatic perturbation \(\sim \exp(-i\omega t + ik_2 b_2 x^2)\) as follows

\[
\begin{align*}
p &= -\xi_h \nabla P_0 - \gamma P_0 \nabla \xi_h, \quad (2.8) \\
E &= i\omega c^{-1} \xi_{c(h)} \times B_0, \quad (2.9) \\
\nabla \times E &= i\omega c^{-1} b, \quad (2.10) \\
-\omega^2 (\rho_0 \xi_h + \rho_c \xi_c) &= -\nabla p - 4\pi^{-1} b \times [\nabla \times B_0] - 4\pi^{-1} B_0 \times [\nabla \times b]. \quad (2.11)
\end{align*}
\]
operators are introduced: noticing that \( \xi_{c1} = \xi_{h1}, \xi_{c2} = \xi_{h2} \) from linearized Eq. (2.6) and \( \xi_{c3} = 0 \) from linearized Eq. (2.3), we denote \( \xi_1 = \xi_{h1}, \xi_2 = \xi_{h2}, \xi_3 = \xi_{h3} \). Excluding the perturbed electric field \( E \) from (2.10), we obtain a closed set of equations for \( b, \xi \) and \( p \):

\[
\begin{align*}
p &= -\xi_1 \nabla_1 P_0 - \gamma P_0 u, \\
b_1 &= h_2^{-1} \nabla_3 h_2 B_0 \xi_1, \\
b_2 &= h_1^{-1} \nabla_3 h_1 B_0 \xi_2, \\
b_3 &= -h_2^{-1} \nabla_1 h_2 B_0 \xi_1 - i B_0 k_2 \xi_2, \\
\omega^2 \rho_0 \xi_1 &= \nabla_1 p + (4\pi h_3)^{-1} b_3 \nabla_1 h_3 B_0 + (4\pi h_3)^{-1} B_0 \nabla_1 h_3 b_3 - (4\pi h_1)^{-1} B_0 \nabla_3 h_1 b_1, \\
\omega^2 \rho_0 \xi_2 &= ik_2 p + ik_2 (4\pi)^{-1} B_0 b_3 - (4\pi h_2)^{-1} B_0 \nabla_3 h_2 b_2, \\
\omega^2 \rho_0 \xi_3 &= \nabla_3 p - (4\pi h_3)^{-1} b_1 \nabla_1 h_3 B_0.
\end{align*}
\]

where \( \rho_0 = \rho_{c0} + \rho_{h0} \), and \( b_1, \xi_1, k_1 \) are scaled components of vectors \( b, \xi, k \) correspondingly.

The variable \( u = \nabla \xi = (h_2 h_3)^{-1} \nabla_1 h_3 h_3 \xi_1 + ik_2 \xi_2 + (h_1 h_2)^{-1} \nabla_3 h_3 h_3 \xi_3 \) characterizes the plasma compression. Substituting the expressions for \( p \) and \( b_1 \) from (2.12) and (2.14) into (2.18), one can find an important relationship between the field-aligned plasma displacement \( \xi_3 \) and the plasma compression \( u \):

\[ \xi_3 = -k_s^{-2} \nabla_3 u, \]

where \( k_s = \omega/V_s \), and \( V_s = \sqrt{\gamma \rho_0/\rho_{h0}} \) is the sound speed determined by hot particles.

Excluding \( b \) from (2.12)–(2.18) and proceeding from \( \xi_3 \) and \( p \) to variables \( u \) and \( \bar{p} \), where \( \bar{p} = 4\pi B_0^{-2} (p + B_0 b_3/4\pi) \) is the normalized perturbation of the total pressure, we obtain the following equations:

\[
\begin{align*}
L_P \xi_1 &= \nabla_1 \bar{p} - \beta \kappa P \bar{p} - \gamma \beta \kappa \epsilon u - \beta \kappa \epsilon \xi_1, \\
L_T \xi_2 &= ik_2 \bar{p}, \\
k_s^{-2} (L_s + \mu k_A^2) u &= -\bar{p} - 2\kappa \xi_1, \\
k_s^{-2} L_s u &= \nabla_1 \xi_1 + ik_2 \xi_2 - \kappa_1 \xi_1 + (\nabla_1 \ln h_2) \xi_1.
\end{align*}
\]

Here \( \mu = \rho_{h0}/\rho_0 \) is the fraction of the hot component, and the following differential operators are introduced:

\[
\begin{align*}
L_P &= k_A^2 + h_2 \nabla_3 h_1 h_2^{-1} \nabla_3 h_1^{-1}, \\
L_T &= k_A^2 + h_1 \nabla_3 h_2 h_1^{-1} \nabla_3 h_2^{-1}, \\
L_s &= k_s^2 (1 + (h_1 h_2)^{-1} \nabla_3 h_1 h_2 k_s^{-2} \nabla_3),
\end{align*}
\]

where \( k_A = \omega/V_A \) is the Alfvén wave number, \( V_A = B_0/\sqrt{4\pi \rho_0} \) is the Alfvén speed. The system (2.19) for one-component plasma coincides with the system derived in (Cheng 2003) for 2D case.

### 2.2. Asymptotic theory of small-scale disturbances

Now we examine the asymptotic solution for the harmonics \( \propto \exp(ik_1 h_1 x^1 + ik_2 h_2 x^2) \) of the system (2.19) for small-scale disturbances in the transverse direction, i.e. for large transverse wave numbers \( k_\perp = (k_1^2 + k_2^2)^{1/2} \rightarrow \infty \). The asymptotic solution of (2.19) we search for in the form (\( n = 1, 2 \))

\[ (\xi_n, u, \bar{p}) = [(\xi_{n0}, u_0, \bar{p}_0) + \varepsilon (\xi_{n1}, u_1, \bar{p}_1) + \varepsilon^2 (\xi_{n2}, u_2, \bar{p}_2) + \ldots] \exp \left[ i \theta (x_1) \varepsilon^{-1} \right], \]
Dispersion equation for ballooning modes in two-component plasma

where \( \varepsilon \) is a small parameter. We put this decomposition into the system (2.19). Collecting terms with the same order of \( \varepsilon \), we get in the order of \( \varepsilon^{-1} \) the system

\[
k_1 \xi_{10} + k_2 \xi_{20} = 0, \quad k_1 \bar{p}_0 = 0, \quad k_2 \bar{p}_0 = 0, \tag{2.20}
\]

from which it follows that the perturbation of the total pressure \( \bar{p} \) is small value of the order of \( \leq \varepsilon \), which means the separation of a fast magnetosonic wave.

Further, in the zeroth order of \( \varepsilon \) we get the system

\[
\begin{align*}
    ik_1 \xi_{11} + \kappa \xi_{10} + (\nabla_1 \ln h_2) \xi_{10} + ik_2 \xi_{21} - k_s^{-2} L_s u_0 &= 0, \\
    (L_P + \beta \kappa, \kappa_P) \xi_{10} + \gamma \beta \kappa_c u_0 + \beta \kappa_p \bar{p}_0 - ik_1 \bar{p}_1 &= 0, \\
    L_T \xi_{20} - ik_2 \bar{p}_0 &= 0, \\
    2 \kappa_c \xi_{10} + k_s^{-2} (L_s + \mu k_A^2) u_0 + \bar{p}_0 &= 0. \tag{2.22}
\end{align*}
\]

Excluding \( \bar{p}_0 \) and \( \xi_{20} \) from (2.22)–(2.24) with the help of equations (2.20) and then excluding also the variable \( \bar{p}_1 \) we obtain the closed system of zero approximation equations (where zero indices are omitted for brevity)

\[
\begin{align*}
    (L_P + k_1^2 k_2^2 L_T + \beta \kappa_c, \kappa_P) \xi_1 + \gamma \beta \kappa_c u &= 0, \\
    2 \kappa_c k_s^2 \xi_1 + (L_s + \mu k_A^2) u &= 0. \tag{2.25}
\end{align*}
\]

This system of ordinary differential equations for the coupled Alfvén and SMS modes describes the ballooning disturbances. These equations in the case of one-component plasma (\( \mu = 1 \)) coincide with equations from (Walker 1987; Klimushkin 1998).

3. Local dispersion equation

The spectral properties of the ballooning modes can be qualitatively understood with the use of local dispersion equations. Let us suppose that a disturbance has a small scale not in the transverse direction only, but also along the field line \( x^3 \).

In the geometrical optics (WKB) approximation \( \propto \exp(ik_3 h_3 x^3) \) all operators turn into numerical factors \( L_P = L_T = k_A^2 - k_s^2 \), where \( k_A^2 \equiv k_3^2 \). Then the local dispersion equation stemming from the system (2.25) has the following form

\[
(\omega^2 - k_A^2 V^2_A)(\omega^2 - k_s^2 V_{ms}^2) + \sin^2 \theta [\beta \kappa_c, \kappa_P V_A^2(\omega^2 - k_A^2 V_{ms}^2) - 4 \omega^2 \mu \kappa_c^2 V_{ms}^2] = 0, \tag{3.1}
\]

where \( \sin^2 \theta = k_2^2/(k_2^2 + k_3^2) \), and \( V_{ms} = V_A^2 V_s^2/(V_A^2 + \mu V_s^2) \) is the characteristic magnetosonic speed.

The important distinction from the case of one-component plasma (\( \mu = 1 \)) is that in a two-component plasma the magnetosonic speed \( V_{ms} \) may exceed the Alfvén speed \( V_A \). This possibility emerges under \( V_s > V_A \) when \( \mu \) is sufficiently small, namely

\[
\mu < 1 - V_A^2/V_s^2. \tag{3.2}
\]

If \( V_s \leq V_A \), then under any \( \mu \) the magnetosonic speed is still less than the Alfvén speed, \( V_{ms} < V_A \). The condition (3.2) can be used during consideration of plasma with fixed temperature of hot component. However, if the parameter \( \beta \) is considered to be fixed, the condition (3.2) should be replaced by \( \mu < \gamma \beta/(2 + \gamma \beta)^{-1} \).

In the cold limit (\( \beta \to 0 \)) the equation (3.1) reduces to the Alfvén dispersion equation in a cold plasma: \( \omega^2 - k_A^2 V_{Ac}^2 = 0 \), where \( V_{Ac} = B_0/\sqrt{4 \pi \rho_c} \). When the hot component predominates over cold ion population, \( \mu \to 1 \), then the equation (3.1) transforms to the dispersion equation for one-component plasma with finite pressure. The obtained local dispersion equation for the axial symmetric case coincides with the equation for 2D case with straight Y-axis.
The equation (3.1) is a quadratic equation in respect to $\omega^2$. The roots $\omega^2$ of (3.1) are real for a real $k$ \[ \frac{V^2}{2 + \gamma \beta} \left( \sigma k^2 + H \pm \sqrt{(\tau k^2 + H)^2 + 4\mu^{-1}\gamma^2 \beta^2 k^2 \sin^2 \theta} \right), \quad (3.3) \]

where $H = \beta \kappa_c [2\gamma \kappa_c - \kappa_p(2 + \gamma \beta)/2] \sin^2 \theta$, $\sigma = 1 + \gamma \beta (\mu^{-1} + 1)/2$, and $\tau = 1 - \gamma \beta (\mu^{-1} - 1)/2$. The relationship (3.3) describes two branches: fast ($\omega_+$), which transforms into an Alfvén wave as $\beta \to 0$, and slow ($\omega_-$) branch.

The fast branch $\omega_+(k) > 0$ is stable for any real $k$. Only the slow mode $\omega_-(k)$ can be unstable under the condition

$\beta \kappa_c \kappa_p \sin^2 \theta > k^2. \quad (3.4)$

This inequality is the generalization of the ballooning instability condition for oblique disturbance $k \neq 0$ (Liu 1997) and has the same form as the instability condition for the slow mode in one-component plasma.

The asymptotic formulas for disturbances with small scales in the field-aligned direction are obtained from (3.3) under assumption $k \gg \kappa \sin \theta$. They depend on the sign of the coefficient $\tau$ in (3.3). When $\mu > \gamma \beta / (2 + \gamma \beta)$ this value is positive, and the asymptotic formulas have the form

$\omega^2_+ = L_A(k^2) + O(k^{-2}), \quad \omega^2_- = L_{ms}(k^2) + O(k^{-2}), \quad (3.5)$

where

$L_A(k^2) = V_A^2 k^2 + V_A^2 \kappa_c \beta \left[ 2 \gamma \left( 1 + \frac{(1 - \mu) \gamma \beta}{\mu(2 + \gamma \beta) - \gamma \beta} \right) - \frac{\kappa_p}{\kappa_c} \right] \sin^2 \theta$

and

$L_{ms}(k^2) = V_{ms}^2 k^2 - \frac{4V_{ms}^2 \kappa_c \gamma \beta \mu \sin^2 \theta}{\mu(2 + \gamma \beta) - \gamma \beta} \quad (3.6)$

Otherwise, if $\mu < \gamma \beta / (2 + \gamma \beta)$, then the characteristic speed $V_{ms}$ exceeds $V_A$, and the asymptotics changes to

$\omega^2_+ = L_{ms}(k^2) + O(k^{-2}), \quad \omega^2_- = L_A(k^2) + O(k^{-2}).$

The oscillation branches may be classified according to their asymptotics in the limit $k \to \infty$. The branch with asymptotics $\omega^2 \approx L_A(k^2)$ may be called Alfvén branch, whereas the branch with asymptotics $\omega^2 \approx L_{ms}(k^2)$ may be called magnetosonic branch. It is worth noting that in a two-component plasma the magnetosonic branch can become a fast branch, which can never happen in a one-component plasma. For that it is necessary the hot component temperature to be rather high, $V_s > V_A$, and the fraction of hot component density to be sufficiently small (see (3.2)).

Alfvén and magnetosonic branches are distinguished not by their speeds only, but by their polarizations as well. Short-wavelength Alfvén waves ($k \to \infty$) are transverse, whereas magnetosonic waves are compressional (see below (3.9) and (3.10)). However, under finite wave number $k$, owing to the mode coupling described by the ballooning system (2.25), this distinction does not hold, and two branches have both transverse and compressional components.

The wave magnetic components can be derived via the variables $\xi_1$ and $u$ from the system (2.25) as follows

$\begin{align*}
  b_3 &= B_0(\beta/2)(\kappa_p \xi_1 + \gamma u), \\
  b_1 &= h^{-1}_2 \nabla_3 (h_2 B_0 \xi_1).
\end{align*}$
From these relationships, and using in the WKB limit $b_1 = i k_{||} B_0 \xi_1$, the ratio between the field-aligned and transverse magnetic components can be derived via the ratio $u/\xi_1$:

$$b_3/b_1 = \beta (2 i k_{||})^{-1} (\kappa_P + \gamma u/\xi_1).$$  \hspace{1cm} (3.7)

For poloidal oscillations, that is if $k_1 \ll k_2$, from the WKB limit of the system (2.25) with account for the dispersion equation (3.1) the ratio $u/\xi_1$ can be found explicitly. Using it in (3.7), we obtain the dependence of the ratio between the compressional and transverse magnetic components on wave number and plasma parameters

$$\frac{b_3}{b_1} = \frac{k_{||}}{2i\kappa_c} \left(1 - \frac{\omega^2}{k_{||}^2 V_A^2} \right),$$  \hspace{1cm} (3.8)

where $\omega^2$ is one of the dispersion equation branches (3.3). At $k_{||} \to \infty$ in accordance with asymptotic formulas (3.5) and (3.6) the ratio $b_3/b_1$ for Alfvénic branch is as follows

$$\frac{b_3}{b_1} \approx \frac{i \beta \kappa_c}{2k_{||}} \left[ 2\gamma - \frac{\kappa_P}{\kappa_c} + \frac{2(1 - \mu)\gamma^2\beta}{\mu(2 + \gamma\beta) - \gamma\beta} \right],$$  \hspace{1cm} (3.9)

whereas for the magnetosonic branch this ratio is

$$\frac{b_3}{b_1} \approx \frac{k_{||}}{2i\kappa_c} \left(1 - \frac{\gamma\beta}{\mu(2 + \gamma\beta)} \right).$$  \hspace{1cm} (3.10)

The analysis of the formula (3.8) shows that in a stable, nearly one-component hot plasma at $\mu > \mu_\beta^* = \gamma\beta/(2 + \gamma\beta)$, the wave polarization corresponds to the mode classification in the short wavelength limit, however at smaller $k_{||}$ it changes to the opposite. At the same time, when hot plasma component is small ($\mu < \mu_\beta^*$) because of the asymptotics swapping at $\mu = \mu_\beta^*$, the Alfvénic branch polarization is predominantly transverse at all $k_{||}$. The same is valid for magnetosonic branch: at small $\mu$ its polarization is predominantly compressional at all $k_{||}$. In a potentially unstable plasma with $\kappa_P/\kappa_c > 0$, the growing slow mode under condition (3.4) has a magnitude of the ratio $b_3/b_1 \approx 1/2$.

\textbf{3.1. The possibility of total reflection of the poloidal Alfvén waves}

Analysis of the dispersion equation (3.3) shows that for the real $\omega$ there may occur regions where $k_0^2 < 0$. These regions with high $\beta$ and locally curved field lines are non-transparent for poloidal Alfvén waves (Mager et al. 2009). A wave meets the turning points $k_0^2 = 0$ when its frequency $\omega$ matches the cut-off frequency

$$\omega^2 = \omega_*^2(0) = \beta V_A^2 \kappa^2 \left( \frac{4\gamma}{2 + \gamma\beta} - \frac{\kappa_P}{\kappa_c} \right) \sin^2 \theta = \frac{2 P_0}{\rho_0} \kappa^2 \left( \frac{4\gamma}{2 + \gamma\beta} - \frac{\kappa_P}{\kappa_c} \right) \sin^2 \theta.$$  \hspace{1cm} (3.11)

When $\kappa_P/\kappa_c \ll 1$, the cut-off frequency distribution along a field line can be estimated as $\omega_*^2 \sim 1/(R^2 \rho_0)$ because $P_0$ is constant along the field line. Both the curvature radius $R_c$ of the field line and the plasma density $\rho_0 = \rho_{e0} + \rho_{i0}$ decrease along the field line from the ionosphere to the equator. The cut-off frequency $\omega_*^2$ monotonically rises equatorward, and if its value at the equator exceeds $\omega^2$, the opaque region around the equator can appear, where $\omega^2 < \omega_*^2$.

For field lines intersecting the plasma sheet, the density after a monotonic fall increases considerably in the plasma sheet region. As a result, it is possible for a transparent region near the equator between two opaque regions to appear. In this case, however, the transparent region at the top of a field line seems to be too narrow to provide a resonator for coupled Alfvén and slow magnetosonic waves. Near the cut-off frequency the Alfvénic branch wavelength is very large, so the occurrence of a finite-scale non-transparent region cannot prevent the tunneling of Alfvénic mode through this region.
4. Dispersion curves for two-component plasma

The dispersion equation for the two-component plasma besides the parameters $\rho_0$, $T$, $B_0$, $\kappa_P$, $\kappa_c$, and $\sin^2 \theta$, holds the new parameter $\mu$. The dependence of dimensionless frequency $\Omega_k = \omega_\pm (\kappa_c V_A \sin \theta)^{-1}$ on dimensionless wave number $\kappa = k(\kappa_c \sin \theta)^{-1}$ for a set of new parameter $\mu$ values is given in Figures 1 - 4. For the taken normalization of frequency and wave number, the asymptotics of the Alfvénic branch have a unit slope, whereas the slope of the magnetosonic branch asymptotics is $V_{ms}^2/V_A^2$. The total density $\rho = \rho_0 + \rho_0$, as well as $V_A$, are supposed to be fixed.

The influence of the hot component on plasma properties may be considered from two viewpoints:

A) the parameter $\beta$ is proportional to $\mu$, while the temperature of the hot component is assumed to be constant;

B) the parameter $\beta$ is fixed ($\beta = 1$ for the examples presented in figures), that is the hot component temperature is inversely proportional to $\mu$.

For the case A the dispersion curves are shown in Figures 1 (stable plasma $\kappa_P/\kappa_c < 0$) and 2 ($\kappa_P/\kappa_c > 0$, when plasma instability is possible). We consider the case when the temperature of the hot component is sufficiently high, so $V_s^2$ exceeds $V_A^2$ ten times. In this case the critical value of $\mu$, when the Alfvénic and magnetosonic branches swap the asymptotics, is $\mu^* = 1 - V_A^2/V_s^2 = 0.9$. Thus, the range of $\mu$ values, when $V_A > V_{ms}$, is rather narrow. For $\mu < 0.9$ the magnetosonic branch is a fast one, whereas the Alfvénic branch is a slow one. The velocity of the magnetosonic branch increases rapidly with the decrease of the hot component fraction $\mu \to 0$: $V_{ms}/V_A = (0.1 + \mu)^{-1/2} \sim \mu^{-1/2}$, until $\mu > 0.1$, up to the limiting velocity $V_s = \sqrt{10} V_A$. This behavior indicates that the fast wave propagation involves the hot component only, which explains the increase of $V_{ms} \propto \rho_{th}^{-1/2}$ upon the decrease of hot component density $\rho_{th}$.

The interval of unstable $k_\parallel$ (Fig. 2) evidently shrinks upon the decrease of $\mu$, and consequently $\beta$, according to the condition (3.4). In a two-component plasma only the slow branch $\omega_-(k_\parallel)$ can be unstable, whereas the fast branch $\omega_+(k_\parallel)$ is always stable.

In the case of the one-component plasma ($\mu = 1$) this conclusion means the stability of Alfvénic mode and possible instability of the magnetosonic mode (Mazur et al. 2012). However, in a two-component plasma under a sufficiently small $\mu$ the association of fast and slow branches with Alfvénic and magnetosonic modes (identified according to their short-wave asymptotics) changes. For an the example given in Fig. 2, it is Alfvénic mode which turns into slow branch at $\mu < 0.9$ and may become unstable. Notice that the polarization of an unstable mode does not correspond to neither pure compressional, nor transverse disturbances, because $|b_3/b_1| \gtrsim 1/2$.

For case B the dispersion curves are shown in Figures 3 and 4. As in case A, the dispersion curves for Alfvénic and magnetosonic modes swap their asymptotics upon the decrease of $\mu$ below the critical value $\mu^*_\gamma = \gamma \beta (2 + \gamma \beta)^{-1}$ (for Figures 3 and 4 $\mu^*_\gamma = 5/11 \approx 0.45$). In contrast to case A, under fixed $\beta$ the asymptotic velocity of the fast branch $V_{ms}/V_A = -\gamma \beta (2 + \gamma \beta)^{-1}$ increases to infinity, because the hot component temperature $\propto \mu^{-1}$. Moreover, under fixed $\beta$ the instability threshold and cut-off frequency do not depend on $\mu$, as they are determined by parameter $\beta$ according to (3.4) and (3.11), which do not hold parameter $\mu$.

4.1. The growth rate of unstable disturbances

The fastest growth rate of unstable disturbances at linear phase ($\propto \exp(\Gamma t)$) is determined by the minimum of $\Omega_\pm^2(\kappa_\parallel)$. From the expression for $\omega_\pm^2$ (3.3) one can find that $\min \Omega_-^2 = -(1/4)\mu^{-1} \Lambda^2 \beta^2 (1 + \lambda)^{-2}$, where $\Lambda = \kappa_P/\kappa_c$, $\lambda = [1 - \tau A(2\gamma)^{-1}]^{1/2}$, and $\tau = (2 + \gamma \beta$
Dispersion equation for ballooning modes in two-component plasma

\[ \frac{\gamma}{\beta} \mu^{-1}/2, \]

is reached at

\[ \kappa^2_\parallel = \frac{\Lambda \beta}{1 + \lambda} \left[ 1 - \frac{(2 + \gamma \beta)\Lambda}{4\gamma(1 + \lambda)} \right]. \]

Thus, the maximal growth rate

\[ \max \Gamma = \frac{1}{2} \mu^{-1/2}(1 + \lambda)^{-1} \beta \kappa P V A \sin \theta. \]

The comparison of \( \min \Omega^2 \) in one-component plasma (\( \mu = 1 \)) and in two-component plasma with small addition of hot component \( \mu \ll 1 \) under the same \( \beta \) gives the ratio

\[ \frac{\min \Omega^2 (\mu \ll 1)}{\min \Omega^2 (\mu = 1)} = \frac{4}{\Lambda \beta} \left( 1 + \sqrt{1 - \Lambda/(2\gamma)} \right)^2. \]

For the parameters \( \Lambda = \beta = 1 \), used in Fig. 4, this ratio is 13.5; therefore the growth rate in the two-component is 3.7 times larger than in the one-component plasma.

5. Discussion

Analysis of the exact dispersion relationship (3.1) in the poloidal limit \( k_1 \to 0 \) shows that the fast branch \( \omega^2_\parallel \) is stable for any \( k^2_\parallel \), that is \( \omega^2_\parallel \geq 0 \). So, the conclusion about a possible instability of the fast mode which in the case of one-component plasma is Alfvén mode (e.g., (Ohtani & Tamao 1993); (Miura et al. 1989)) cannot be accepted.

Under favorable conditions for the balloon instability on field lines, strongly extended into the magnetotail, the disturbance grows exponentially, though drift effects may produce oscillatory growth and azimuthal drift with the velocity about the Larmor drift velocity (Miura et al. 1989). The characteristic growth time of the instability, \( \tau \simeq \Gamma^{-1} \simeq 30 \) s, is about the typical time scale of the substorm explosive phase. However, an estimation of the instability criterion in the WKB approximation for a particular magnetic shell has an ultimately qualitative character. In a realistic magnetosphere, the ballooning modes are to be localized near the top of the field line, where the \( \beta \) and curvature rapidly increase. However, \( k_\parallel \to \infty \) in fact corresponds to the homogeneous case, and in this case the instability is absent according to (3.4).

The typical time scale of the substorm explosive phase (~1-2 min) is much less than the Alfvén transit time along the extended field lines from the magnetotail to the ionosphere (~10 min). Therefore, the influence of the ionospheric boundaries on the ballooning mode properties can be neglected, assuming that the growing disturbances are localized in the near-equatorial region of the nightside magnetosphere. The influence of the ionospheric boundary conditions on the ballooning modes was considered in many papers (e.g., Cheremnykh & Parnowski 2006). The imposing of boundary conditions at conjugate ionosphere results in quantization of \( k_\parallel \) and occurrence of its imaginary components.

For the considered model the source of the free energy for the ballooning instability is the excess of the hot plasma pressure in the radial direction. However, this 2D model does not take into account certain factors which might be significant for the instability development: pressure anisotropy (Cheng & Qian 1994), drift effect (Pokotelov et al. 1980), kinetic effects (Klimushkin & Mager 2008), and the azimuthal pressure gradient related to a background field-aligned current (Ivanov et al. 1992; Golovchanskaya & Mingalev 2006).
6. Conclusion

The principal new feature of the two-component plasma is the possibility for a sound wave to propagate via the hot component only, whereas Alfvénic oscillations involve all plasma particles. This feature changes the dispersion curves for Alfvénic and slow magnetosonic modes drastically, especially when the hot component fraction is small, and violates the correspondence between fast/slow branches and Alfvénic/magnetosonic modes.

In the region with a steep drop of the plasma pressure, held by curved magnetic field lines, an instability of the slow mode may become feasible. For fast waves with frequencies less than the cut-off frequency a non-transparent region may occur, which can influence the wave propagation along a field line.
